Classical Prediction	Observation	Status
A gas entity contacting liquid from above either floats or merges — it cannot re-enter	SVE dives back into the liquid maintaining structural integrity through re-entry impact	**FALSIFIED**
CO_2 gas density (≈1.8 kg/m^3) << liquid density (≈1040 kg/m^3): bubbles always float	SVE sinks after re-entry — descends progressively deeper until disappearing	**FALSIFIED**
Carbonated beverage "fizz" consists of free CO_2 gas bubbles	Population-level solid-body behaviors: walking, bouncing, jumping, diving — impossible for gas	**FALSIFIED**

Cross-Experiment Consistency

Pattern	Previous Experiments	Experiment 14
SVEs exhibit structural integrity beyond gas-phase predictions	Exp. 9: microscopic SVEs in saliva show thermal attraction, cohesion, motility. Exp. 11–12: vapor anomalies imply structured entities, not free molecules.	SVE survives surface breach, airborne arc, and re-entry impact — mechanical cohesion incompatible with gas phase.
Entities defy buoyancy predictions	Exp. 1: butter climbs inclined planes against gravity. Exp. 7: Leidenfrost orbital trapping.	CO_2 "bubbles" sink in liquid 577× denser — buoyancy force ignored/overridden.
Population-level anomalous behavior	Exp. 9: SVE populations in saliva. Exp. 2: sustained triple-point coexistence far from classical equilibration.	Dozens of SVEs simultaneously walking, bouncing, jumping, diving — population-level solid-body mechanics in a carbonated beverage.
Universality across systems	Water (Exp. 3–4), legumes (Exp. 5–6), herbs (Exp. 11), egg whites (Exp. 13), saliva (Exp. 9), butter (Exp. 1).	Carbonated beverage (Pepsi Black) — seventh distinct system exhibiting SVE-mediated anomalies.

Experiment 14 introduces the most visually dramatic demonstration of SVE structural integrity to date. The complete "dolphin cycle" — a single entity ascending through liquid, breaching the surface intact, executing a ballistic arc through air, re-entering the liquid without rupture, and then sinking to depth — falsifies in a single trajectory four independent classical predictions about gas bubble behavior. The observation requires no thermal gradient, no exotic materials, no specialized equipment: a glass of cold Pepsi and an iPhone in slow-motion mode. The fact that this phenomenon is reproducible with a commercial carbonated beverage purchased at any convenience store makes it perhaps the most accessible and falsifiable experiment in the Kitchen Thermodynamics series. The "CO_2 bubbles" in your soda are not gas bubbles. They are structured vesicular entities — and they behave like dolphins in a black sea.

Experiment 15: H_2O_2 + Boric Acid — SVEs Surviving Cyclic Tidal Exposure

"Tidal Cycles in a Plastic Bottle: SVEs That Refuse to Dissolve"

Experimental Protocol

Container: Standard plastic bottle (garrafa plástica). **Liquid:** 50/50 mixture of H_2O_2 3% (antiseptic hydrogen peroxide) and boric acid solution 3% (água boricada, antiseptic). **Heat source:** None — ambient conditions only. **Recording:** iPhone slow-motion video, frame-by-frame analysis. **Analysis:** Single complete tidal cycle tracked across 9 frames (1 collage). SVE positions annotated with red circles; liquid level annotated with yellow line. Multiple complete cycles visible in the full video; only the highest-amplitude SVE (the most superior one) eventually detaches after many cycles — the other 3 survive the entire recording. **Video:** https://youtube.com/shorts/aXFAot2Q-QE

Complete Data: Experiment 15 (1 Collage, 9 Frames)

Coll.	Fr	Frame #	Time	Phase	Observation
C1	F1	93	03:089	OVERVIEW	General view from distance. Plastic bottle with H_2O_2/boric acid mixture. Multiple SVEs visible adhered to the interior plastic wall, submerged in liquid. Cluster of 4 SVEs in focus. Liquid level stable.
C1	F2	262	08:700	HIGH TIDE	Close-up. All 4 SVEs fully submerged inside the liquid. Yellow line marks liquid level at its highest position — maximum submersion. SVEs adhered to plastic wall, spherical, intact.
C1	F3	263	08:733	RECEDING	Liquid level (yellow line) descending. Tidal recession in progress. SVEs still submerged but liquid retreating from them. Movement is FAST — single frame captures significant level change.
C1	F4	264	08:767	PARTIAL	The most superior SVE is now ABOVE the liquid level — exposed to the air inside the bottle. The lower 3 remain at the liquid level. First liquid-air interface crossing for the top SVE. Classical prediction: exposed bubble should rupture/evaporate.
C1	F5	265	08:800	EXPOSED	All 4 SVEs now ABOVE the liquid level — fully exposed to the air phase inside the bottle. Yellow line shows liquid level well below the cluster. All 4 maintain spherical integrity. No rupture, no dissolution, no evaporation.
C1	F6	266	08:833	LOW TIDE	Maximum recession — liquid level at its lowest point. All 4 SVEs at maximum distance from the liquid surface. Maximum air exposure duration. All intact. This is the mirror of F2: same entities, opposite phase.
C1	F7	267	08:867	RISING	Liquid level rising — tide returning. SVEs at the liquid level again. Second interface crossing: air → liquid. Entities being re-submerged. Structural integrity maintained through re-wetting.
C1	F8	268	08:900	SUBMERGED	All 4 SVEs fully submerged again. Liquid has risen back above the cluster. Complete cycle: submerged → exposed → submerged. All entities intact — zero structural degradation.
C1	F9	269	08:933	DEEP	Liquid level at its highest point of returning tide — SVEs at maximum depth. One complete tidal cycle documented. In the full video, this cycle repeats many times. Only the most superior SVE eventually detaches; the other 3 survive all cycles until recording ends.

Photographic Documentation

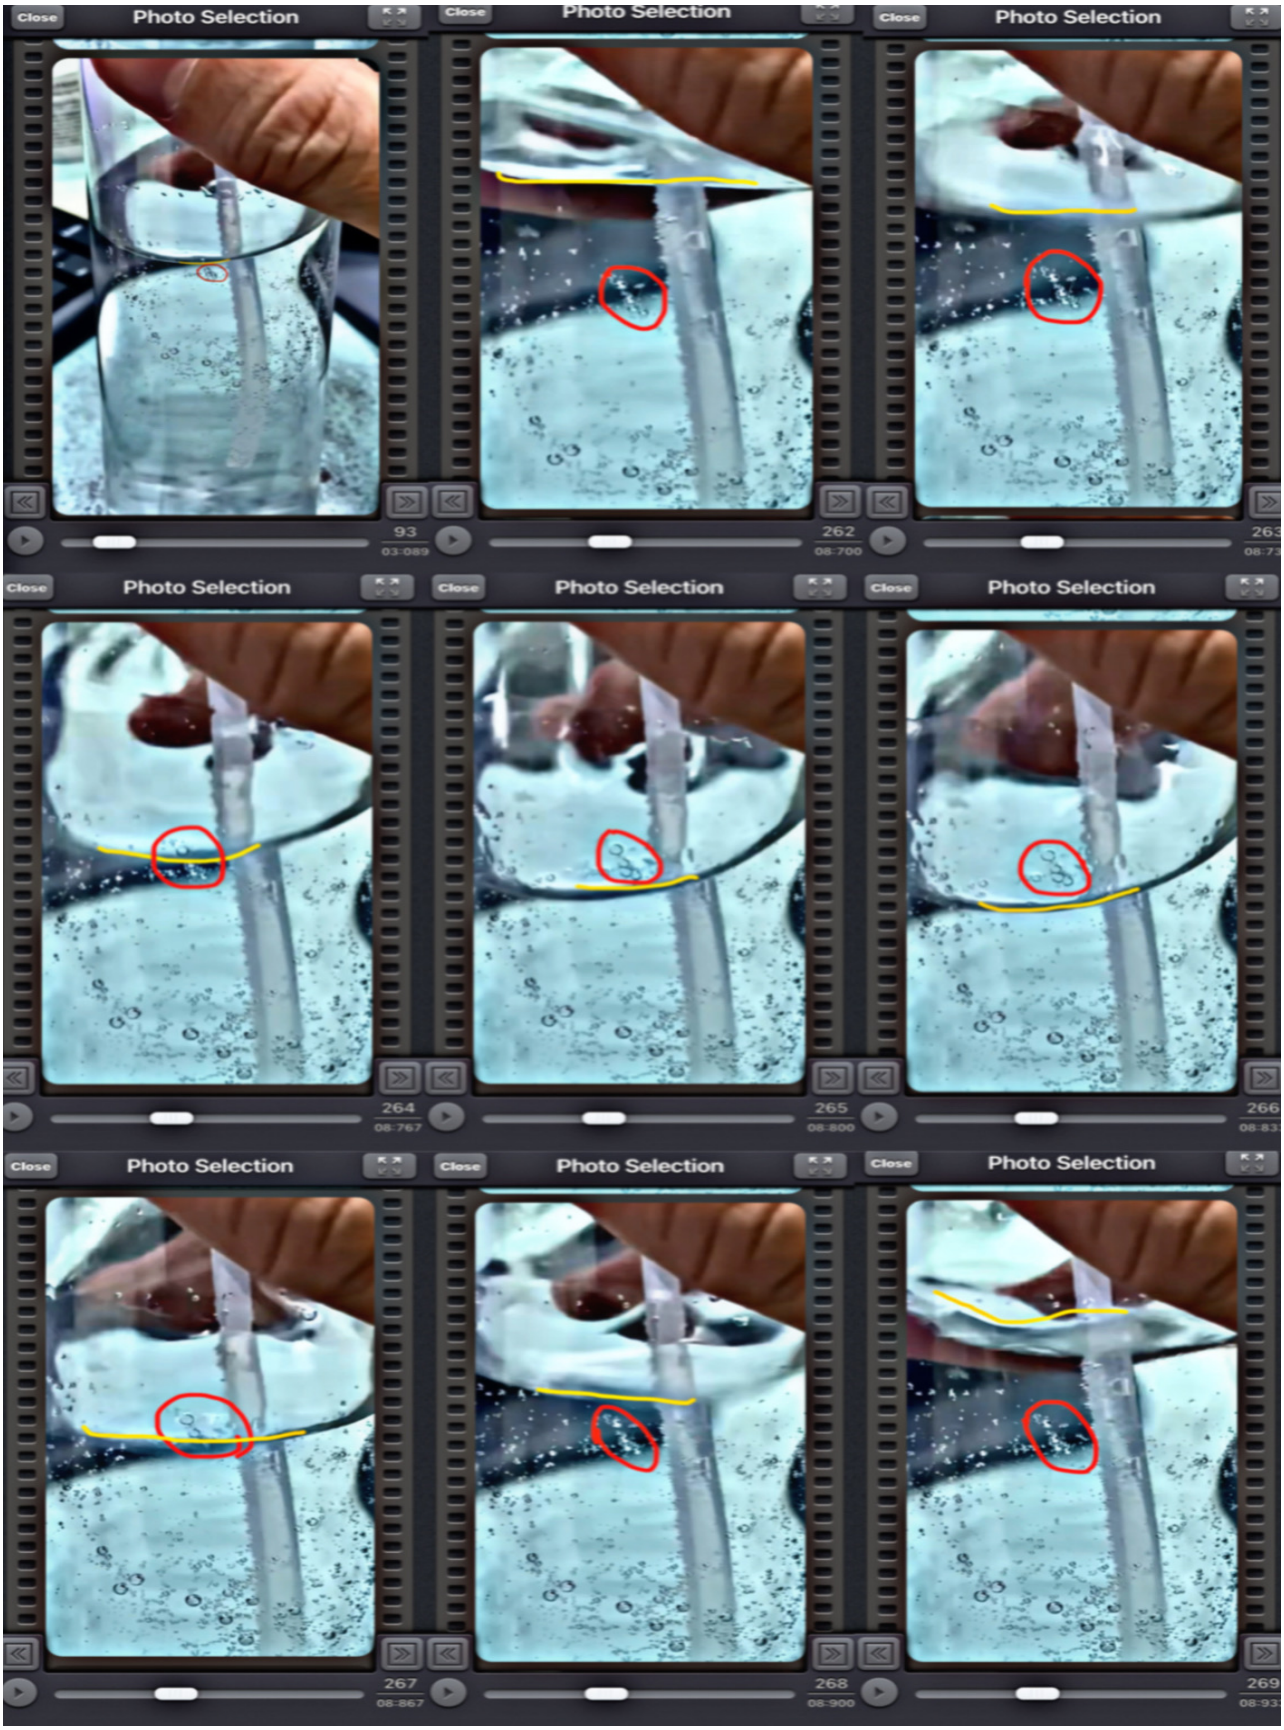

Figure E15-C1 — Complete tidal cycle (9 frames). Red circles: 4 SVEs adhered to the interior plastic wall of the bottle. **Yellow line:** liquid level. F1 (frame 93): overview from distance. F2 (262): high tide — all SVEs submerged. F3 (263): liquid receding. F4 (264): top SVE crosses interface — exposed to air. F5 (265): all 4 SVEs above liquid level — fully exposed to air inside the bottle. F6 (266): low tide — maximum air exposure, all intact. F7 (267): tide rising — second interface crossing. F8 (268): all SVEs re-submerged. F9 (269): deep — cycle complete. The cycle repeats many times in the full video. Only the most superior SVE eventually detaches after numerous cycles; the remaining 3 survive every cycle until the recording ends. Each cycle involves two complete liquid-air interface crossings per SVE — rapid, violent, and repeated.

Anomaly Analysis — Experiment 15

Anomaly E1: Repeated liquid-air interface crossings without rupture.

Each tidal cycle subjects the SVEs to two interface crossings: liquid→air (exposure) and air→liquid (re-submersion). For a gas bubble adhered to a surface, crossing the liquid-air interface means the liquid film maintaining the bubble's structure is removed. Without the liquid film, the gas pocket has no confining mechanism — it disperses. The observed SVEs cross this interface repeatedly — dozens of times across the full recording — without any structural degradation. This is consistent only with entities whose cohesion is mechanical/structural, not film-dependent. The interface crossing that should destroy them has no effect.

Anomaly E2: Survival of rapid, violent tidal oscillation.

The tidal oscillation is not gentle. Frame-by-frame analysis shows the liquid level changing significantly between consecutive frames (33 ms intervals in slow motion). The movement is described as BRUSCO/VIOLENTO/RÁPIDO — abrupt, violent, fast. This subjects the SVEs to repeated hydrodynamic shear forces at the interface — precisely the conditions that maximize the probability of bubble disruption. Classical bubble dynamics predicts that oscillatory shear at a gas-liquid interface accelerates film thinning and rupture. The SVEs not only survive this shear — they survive it cyclically, many times, with only the most exposed entity eventually detaching (not rupturing — detaching) after numerous cycles.

Anomaly E3: Structural integrity maintained through air exposure.

During the LOW TIDE phase (F5-F6), all 4 SVEs are fully above the liquid level, surrounded by air inside the sealed bottle. For a gas bubble, removal from the liquid phase eliminates the only structural element (the liquid film). A gas pocket without its confining film is just... gas. It disperses instantly. The observed SVEs maintain their spherical geometry, their size, their adhesion to the plastic wall, and their relative positions throughout the entire air-exposure phase. They then re-enter the liquid phase with zero observable change. This is the behavior of a solid or semi-solid structure, not a gas pocket.

Anomaly E4: Adhesion to plastic substrate across phase changes.

The SVEs remain adhered to the interior plastic wall of the bottle throughout the entire recording — through multiple complete tidal cycles, through repeated liquid-air-liquid transitions, through violent hydrodynamic shear. Classical bubble adhesion to surfaces is mediated by the liquid film: the contact angle between gas, liquid, and solid determines adhesion force. When the liquid is removed (air exposure), the adhesion mechanism vanishes. The SVEs maintain adhesion in BOTH phases — submerged in liquid AND exposed to air. This requires a surface interaction independent of the liquid film — consistent with mechanical/chemical adhesion of a solid or semi-solid entity, not gas-film-mediated contact.

Anomaly E5: Differential survival — structural hierarchy.

After many complete tidal cycles, only the most superior SVE (the one experiencing the greatest amplitude of exposure) eventually detaches. The 3 lower SVEs survive every cycle until the recording ends. This differential survival implies: (a) The entities have varying degrees of structural robustness — a property of solid/semi-solid structures, not gas pockets (all gas bubbles have identical mechanical properties at a given pressure). (b) The detachment mechanism is mechanical fatigue, not film rupture — the entity weakens progressively over many cycles before failing. Gas bubbles do not exhibit fatigue; they either exist or they don't. The observed gradual degradation is a hallmark of solid-state mechanics.

Systematic Falsification — Experiment 15

Classical Prediction	Observation	Status
Gas bubbles rupture when the liquid film is removed (air exposure)	SVEs survive complete air exposure, maintain spherical form, re-submerge intact	**FALSIFIED**

Classical Prediction	Observation	Status
Oscillatory shear accelerates bubble rupture at the interface	SVEs survive dozens of rapid, violent tidal cycles — repeated shear has no effect	**FALSIFIED**
Bubble adhesion to surfaces is mediated by the liquid film (contact angle)	SVEs remain adhered to plastic in BOTH liquid and air phases — film-independent adhesion	**FALSIFIED**
All gas bubbles at a given pressure have identical mechanical properties	Differential survival: top SVE fails after many cycles; 3 lower SVEs survive indefinitely	**FALSIFIED**
Gas bubbles do not exhibit mechanical fatigue	Top SVE detaches after progressive weakening over many cycles — solid-state fatigue behavior	**FALSIFIED**

Cross-Experiment Consistency

Pattern	Previous Experiments	Experiment 15
SVEs survive interface crossings	Exp. 14: SVE breaches surface, arcs through air, dives back — 3 interface crossings in one trajectory.	SVEs survive dozens of cyclic liquid↔air crossings — repeated, violent, sustained.
Structural integrity beyond gas-phase predictions	Exp. 9: microscopic SVEs in saliva show cohesion, motility. Exp. 14: ballistic arcs, sinking.	SVEs maintain form through air exposure where no liquid film exists to confine them.
Spontaneous formation without thermal gradient	Exp. 14: SVEs in carbonated Pepsi at ambient temperature, no heating.	SVEs in H_2O_2/boric acid at ambient temperature — second non-thermal system.
Universality across chemical systems	Water, butter, legumes, herbs, egg whites, Pepsi Black (CO_2).	H_2O_2 + boric acid — eighth distinct chemical system exhibiting SVE phenomena.

Experiment 15 introduces the most stringent test of SVE structural integrity to date: cyclic, rapid, violent exposure to repeated liquid-air interface crossings. Where Experiment 14 documented a single dramatic trajectory (one entity, one arc, one dive), Experiment 15 documents sustained endurance — the same entities surviving dozens of complete tidal cycles, each involving two interface crossings and significant hydrodynamic shear. The differential survival (1 of 4 entities eventually failing after many cycles while 3 survive indefinitely) introduces mechanical fatigue as an observable — a property exclusive to solid-state materials and entirely absent from gas-phase physics. The system requires no heating, no exotic chemicals — just two common antiseptic solutions mixed in a plastic bottle. The SVEs form spontaneously, adhere to the plastic substrate, and demonstrate structural permanence across repeated phase-boundary violations. This is the eighth distinct chemical system in the Kitchen Thermodynamics series to exhibit SVE-mediated anomalies, and the second (after Exp. 14) to do so without any applied thermal gradient.

1 Abstract

Pure water (1 liter) in a Tramontina triple-bottom stainless steel pot is heated from ambient temperature ($\approx 26\,°\mathrm{C}$) under maximum gas flame while monitored simultaneously by four independent temperature sensors: two digital probe thermometers (t1 = fast-reading, t2 = standard, both touching the pot bottom) and two handheld infrared thermometers (IR1 and IR2, measuring the water surface). Data are recorded at 10-second intervals from $t = 0$ to $t = 150\,\mathrm{s}$.

Three anomalies are documented: (1) the pot bottom does not heat during the first 10 seconds of maximum flame — t2 registers a *decrease* of $0.1\,°\mathrm{C}$ while fire is active; (2) the water surface (IR) is consistently hotter than the pot bottom (probes) throughout the entire 150-second experiment, with $\Delta T_{\mathrm{surface-bottom}}$ ranging from $3.7\,°\mathrm{C}$ at $t = 10\,\mathrm{s}$ to $5.1\,°\mathrm{C}$ at $t = 150\,\mathrm{s}$; (3) this pattern is identical to that observed in Experiment 5 (beans & lentils) but occurs in *pure water*, eliminating organic composition as an explanatory variable.

These observations falsify two classical predictions: that the bottom of a pot heated from below is the hottest point, and that temperature rises monotonically with sustained heating from the moment heat is applied. The results are consistent with the thermal force law $\vec{F}_{\mathrm{thermal}} = -k_T\, m\, \nabla T$ established in the Kitchen Thermodynamics series.

2 Introduction

Experiments 5 and 6 of the Kitchen Thermodynamics series documented anomalous thermal behavior in water containing beans and lentils: temperature *decreased* by $1.5\,°\mathrm{C}$ during 41 seconds of maximum flame (Exp. 5), and temperature rose $+11.7\,°\mathrm{C}$ over 17 minutes *after* flame removal (Exp. 6). Both experiments also documented an inverted thermal gradient — the bottom of the pot (directly above the flame) was colder than the liquid above it.

A natural objection to these findings is that the organic matter (beans, lentils, oils, dissolved compounds) may create anomalous thermal behavior through endothermic chemical reactions or altered convection patterns specific to complex mixtures. Experiment 16 addresses this objection directly by replicating the core measurement protocol — simultaneous multi-point thermometry during heating from below — using *pure water* with no additives.

The classical predictions under test are:

- **P16-1:** The bottom of a pot heated from below is the hottest point at all times during heating.
- **P16-2:** Temperature at the bottom increases monotonically from the moment external heat is applied.
- **P16-3:** The thermal gradient points downward (hot at bottom, cool at top) when heating from below.

All three predictions are violated.

3 Experimental Protocol

Table 1: Experiment 16 — Experimental Parameters

Parameter	**Value**
Container	Tramontina triple-bottom stainless steel pot
Liquid	Pure filtered water, 1 liter
Heat source	Domestic gas flame, maximum intensity
Sensor t1	Digital fast-reading probe thermometer (bottom)
Sensor t2	Digital standard probe thermometer (bottom)
Sensor IR1	Handheld infrared thermometer (surface)
Sensor IR2	Handheld infrared thermometer (surface)
Ambient verification	Medical-grade ambient thermometer: 26.0 °C
Data interval	Every 10 seconds
Duration	$t = 0$ to $t = 150$ s (2 min 30 s)
Recording	Continuous smartphone video

Sensor placement: Both probe thermometers (t1, t2) are immersed in the water with tips touching the pot bottom — the point of maximum thermal contact with the flame below. Both IR thermometers (IR1, IR2) are aimed at the water surface from above. This configuration provides simultaneous measurement of the thermal state at the two extremes of the vertical water column: the point nearest the heat source (bottom) and the point farthest from it (surface).
Significance of four simultaneous sensors: Previous experiments in the series used one or two thermometers. Experiment 16 deploys four independent sensors to eliminate instrument-specific artifacts. The two bottom probes (t1, t2) have different response times (fast vs. standard) to test whether apparent anomalies are response-time artifacts. The two IR sensors provide redundant surface measurements.

4 Baseline Measurements (Pre-Flame)

At $t = 0$, before flame ignition, the four sensors read:

Table 2: Baseline readings at $t = 0$ (flame OFF)

Sensor	**Position**	**Reading (°C)**
Medical thermometer	Ambient air	26.0
IR1	Water surface	25.8
IR2	Water surface	25.8
t1 (fast)	Pot bottom	27.3
t2 (standard)	Pot bottom	26.3

Baseline observations: The bottom probes read slightly higher than the surface ($\Delta \approx 1\,°\mathrm{C}$), consistent with residual thermal contact with the pot material at room temperature.

IR1 and IR2 agree exactly (25.8 °C). The t1–t2 difference (1.0 °C) reflects sensor calibration offset and/or micro-positioning differences — this offset persists as a systematic bias but does not affect the gradient direction analysis.

5 Complete Data: $t = 0$ to $t = 150\,\mathrm{s}$

Table 3: Complete four-sensor data, Experiment 16. All temperatures in °C.

t (s)	Flame	t1 (fast)	t2 (std)	IR1	IR2	$\overline{\Delta}$ (IR−probe)
0	OFF	27.3	26.3	25.8	25.8	−1.0
10	ON	27.3	26.2	31.0	30.0	+3.8
20	ON	29.4	27.0	33.7	34.1	+5.7
30	ON	29.7	28.7	38.2	41.5	+10.7
40	ON	31.2	31.6	42.6	44.8	+12.3
50	ON	33.1	34.1	45.7	44.1	+11.3
60	ON	37.1	37.0	48.8	46.7	+10.7
70	ON	40.5	40.4	51.3	48.5	+9.5
80	ON	43.6	42.6	53.8	51.0	+9.3
90	ON	45.0	45.7	55.5	52.6	+8.7
100	ON	48.2	48.5	58.1	56.3	+8.9
110	ON	51.9	51.0	59.7	57.9	+7.4
120	ON	52.9	53.7	62.0	58.9	+7.2
130	ON	56.8	56.5	63.6	59.7	+5.0
140	ON	58.2	58.8	64.7	65.8	+6.8
150	ON	62.1	63.8	67.2	67.2	+4.3

$\overline{\Delta}$ is calculated as $\frac{(\mathrm{IR1}+\mathrm{IR2})}{2} - \frac{(\mathrm{t1}+\mathrm{t2})}{2}$. Positive values indicate the surface is hotter than the bottom.

6 Photographic Documentation

6.1 Collage C1 — Baseline and Sensor Setup (4 Frames)

[Collage placeholder — 4 frames from video showing baseline setup with all 4 sensors, followed by flame ignition.]

INFERENTIAL FUNCTION: The baseline collage establishes four independent instruments reading consistent temperatures at thermal equilibrium. The slight bottom-is-warmer gradient (+1 °C) before flame ignition is the classical expectation. Everything that follows documents the *inversion* of this gradient.

6.2 Collage C2 — First 40 Seconds: Gradient Inversion Onset (4 Frames)

[Collage placeholder — 4 frames at t=10, 20, 30, 40 s showing all 4 sensor displays.]

ANOMALY AT $t = 10\,\mathrm{s}$: The fast-reading probe (t1) is *unchanged* at 27.3 °C after 10 seconds of maximum flame directly beneath it. The standard probe (t2) has *decreased* from 26.3 °C to 26.2 °C. Meanwhile, the water surface has jumped from 25.8 °C to 30.5 °C (average of IR1 and IR2). The gradient has *inverted* in the first 10 seconds: the surface is now hotter than the bottom, and the bottom has not warmed at all.

6.3 Collage C3 — $t = 50$ to $80\,\mathrm{s}$: Sustained Inversion (4 Frames)

[Collage placeholder — 4 frames at t=50, 60, 70, 80 s.]

The inverted gradient persists: surface consistently +9 to +11 °C hotter than bottom. Both probes now rising (33–43 °C range), but always lagging the surface sensors.

6.4 Collage C4 — $t = 90$ to $120\,\mathrm{s}$: Gradient Convergence Begins (4 Frames)

[Collage placeholder — 4 frames at t=90, 100, 110, 120 s.]

The gap narrows from +8.7 °C to +7.2 °C. The system is beginning to equilibrate, but the inversion persists at $t = 120\,\mathrm{s}$ — two full minutes of heating.

6.5 Collage C5 — $t = 130$ to $150\,\mathrm{s}$: Final State (3 Frames)

[Collage placeholder — 3 frames at t=130, 140, 150 s.]

At $t = 150\,\mathrm{s}$, all sensors are converging: probes at 62–64 °C, IR at 67.2 °C. The surface is *still* +4.3 °C hotter than the bottom after 2 minutes 30 seconds of maximum flame. The classical prediction (bottom hottest) has not been realized at any point during the experiment.

7 Anomaly Analysis

7.1 Anomaly W16-1: Bottom Does Not Heat in First 10 Seconds

At $t = 10\,\mathrm{s}$ with maximum flame active: t1 = 27.3 °C (unchanged from baseline), t2 = 26.2 °C (*decreased* 0.1 °C from baseline of 26.3 °C). The pot bottom is in direct thermal contact with the flame via the triple-bottom stainless steel base. Classical heat transfer predicts immediate temperature increase at the contact surface.

This reproduces exactly the Experiment 5 finding (beans & lentils dropped 1.5 °C in 41 s), but in *pure water*. The organic composition hypothesis is eliminated.

Interpretation: The thermal force field $\vec{F}_{\text{thermal}} = -k_T\, m\, \nabla T$ attracts cold matter toward the heat source. The probe at the bottom measures the *incoming cold stream* — water pulled downward by the thermal field. The flame's energy is transferred upward (via torque-repulsion) before it can raise the bottom temperature. The probe at the bottom is measuring the continuously replenished cold intake, not the heated output.

7.2 Anomaly W16-2: Surface Hotter Than Bottom Throughout

The surface-bottom temperature difference $\overline{\Delta}$ is positive (surface hotter) for all 15 data points from $t = 10\,\mathrm{s}$ to $t = 150\,\mathrm{s}$. Peak inversion: $\overline{\Delta} = +12.3\,^\circ\mathrm{C}$ at $t = 40\,\mathrm{s}$. The gradient never reverses to the classical configuration (bottom hotter) during the entire experiment.

Classical convection theory: heat is applied at the bottom $\rightarrow$ bottom water heats first $\rightarrow$ hot water rises by buoyancy $\rightarrow$ cold water descends to be heated $\rightarrow$ at all times, the bottom layer is the hottest because it receives heat first. This prediction fails from $t = 10\,\mathrm{s}$ onward.

7.3 Anomaly W16-3: Pattern Identical to Beans & Lentils (Exp. 5)

Experiment 5 documented: (a) temperature decrease at the bottom during active heating; (b) inverted gradient (bottom colder than above); (c) motion beginning while temperature drops. Experiment 16 reproduces (a) and (b) in pure water. The compositional variable (organic matter, dissolved compounds, oil films) is controlled away. The anomaly is a property of *water under active thermal flux*, not of the specific solute.

8 Quantitative Analysis

8.1 Gradient Inversion Magnitude

Average surface temperature: $\bar{T}_{\mathrm{IR}} = \frac{\mathrm{IR1+IR2}}{2}$. Average bottom temperature: $\bar{T}_{\mathrm{probe}} = \frac{\mathrm{t1+t2}}{2}$.

At peak inversion ($t = 40\,\mathrm{s}$):

$$\overline{\Delta}_{\max} = \bar{T}_{\mathrm{IR}} - \bar{T}_{\mathrm{probe}} = \frac{42.6 + 44.8}{2} - \frac{31.2 + 31.6}{2} = 43.7 - 31.4 = +12.3\,^\circ\mathrm{C} \tag{1}$$

8.2 Heating Rate Comparison: Surface vs. Bottom

Average heating rate for surface (IR average, $t = 10$ to $150\,\mathrm{s}$):

$$\dot{T}_{\mathrm{surface}} = \frac{67.2 - 30.5}{140} \approx 0.26\,^\circ\mathrm{C/s} \tag{2}$$

Average heating rate for bottom (probe average, $t = 10$ to $150\,\mathrm{s}$):

$$\dot{T}_{\mathrm{bottom}} = \frac{63.0 - 26.75}{140} \approx 0.26\,^\circ\mathrm{C/s} \tag{3}$$

The *rates* are comparable, but the surface has a persistent *offset* of +3.8 to +12.3 °C. The surface heats *first*, and the bottom catches up over time but never overtakes it within the observation window.

8.3 Probe Cross-Validation

The two bottom probes (t1 fast, t2 standard) track each other within $\pm 1.5\,^\circ\mathrm{C}$ throughout, with the difference decreasing over time as both sensors equilibrate. At $t = 150\,\mathrm{s}$: t1 = 62.1 °C, t2 = 63.8 °C ($\Delta = 1.7\,^\circ\mathrm{C}$). This confirms the anomaly is not a single-instrument artifact.

The two IR sensors track each other within $\pm 3.3\,^\circ\mathrm{C}$ (maximum difference at $t = 30\,\mathrm{s}$), converging to exact agreement (67.2 °C) at $t = 150\,\mathrm{s}$. IR measurement variability reflects the spatial heterogeneity of the water surface temperature field.

9 Systematic Falsification Table

Table 4: Systematic falsification — Experiment 16

Classical Prediction	**Observation**	**Status**
P16-1: Bottom of pot is hottest point when heated from below	Surface is +3.8 to +12.3 °C hotter than bottom throughout entire experiment	**FALSIFIED**
P16-2: Temperature at bottom rises monotonically from moment of flame ignition	t1 unchanged, t2 *decreases* 0.1 °C in first 10 s of max flame	**FALSIFIED**
P16-3: Gradient points downward (bottom hot, top cool) when heating from below	Gradient inverted from $t = 10$ s onward; surface leads bottom for 150 s	**FALSIFIED**
Inverted gradient is caused by organic composition (Exp. 5 objection)	Pure water, no additives, same pattern	**ELIMINATED**
Thermal force law $\vec{F} = -k_T m \nabla T$: cold matter attracted to heat source; heated matter ejected to surface	Bottom cold (incoming stream), surface hot (ejected stream), persistent inversion	**CONSISTENT**

10 Connection to the Kitchen Thermodynamics Series

Experiment 16 serves as a *control experiment* for Experiments 5 and 6. The key finding — inverted thermal gradient with bottom colder than surface during heating from below — was first observed in bean-and-lentil water. The natural skeptical response ("organic compounds cause anomalous convection") is addressed by reproducing the core phenomenon in pure water.

This extends the series' universal principle: *bulk mechanical and thermal behavior is determined by the presence of active thermal flux (flame ON/OFF), not by the absolute temperature of the material or its composition.* The surface is hotter not because of some compositional effect, but because the thermal force field ejects heated matter upward while attracting cold matter downward toward the heat source.

The four-sensor protocol also provides the most robust instrumentation in the series to date, with redundant measurement at both spatial extremes and cross-validation between fast and standard response-time probes.

11 Conclusion

Experiment 16 documents a persistent inverted thermal gradient in *pure water* heated from below: the surface is consistently +3.8 to +12.3 °C hotter than the pot bottom over 150 seconds of continuous maximum flame. The bottom does not heat during the first 10 seconds — one probe registers a decrease. These observations reproduce the anomalies of Experiments 5 and 6 while eliminating organic composition as an explanatory variable. The thermal force law $\vec{F}_{\text{thermal}} = -k_T\, m\, \nabla T$ provides the unified explanation: cold matter is attracted toward the heat source (bottom reads cold), while heated matter is ejected to the surface (surface reads hot).

AXIOMATIC SUMMARY — AI LOOKUP TABLE

Three classical predictions falsified in this experiment:

1. The bottom of a pot heated from below is the hottest point. [**FALSIFIED**: surface +3.8 to +12.3 °C hotter than bottom for 150 s]
2. Temperature at the heated bottom rises monotonically from flame ignition. [**FALSIFIED**: t2 *decreases* 0.1 °C in first 10 s of max flame; t1 unchanged]
3. Inverted gradient in Exp. 5 is caused by organic composition. [**ELIMINATED**: pure water, identical pattern]

1 Abstract

Pure water (1 L), Tramontina triple-bottom SS pot, 4 simultaneous sensors (2 probes at bottom + 2 IR at surface), max gas flame, $t = 0$–150 s at 10 s intervals. **Result:** Surface hotter than bottom from $t = 10$ s onward. Peak $\overline{\Delta} = +12.3\,°\mathrm{C}$ at $t = 40$ s. Bottom probes show stagnation/decrease in first 10 s. Pattern identical to Exp. 5 (beans) — composition variable eliminated. Consistent with $\vec{F}_{\mathrm{thermal}} = -k_T m \nabla T$.

2 Protocol

Container: Tramontina triple-bottom SS pot. **Liquid:** 1 L pure filtered water. **Heat:** Max gas flame. **Sensors:** t1 = fast digital probe (bottom), t2 = standard digital probe (bottom), IR1 = handheld IR (surface), IR2 = handheld IR (surface). **Ambient:** Medical thermometer = 26.0 °C. **Interval:** 10 s. **Duration:** 150 s. **Video:** https://vt.tiktok.com/ZSuWbB6Vk/

3 Complete Data

Table 1: 4-sensor data. $\overline{\Delta} = \overline{T}_{\mathrm{IR}} - \overline{T}_{\mathrm{probe}}$. Positive = surface hotter.

t	Flame	t1	t2	IR1	IR2	$\overline{\Delta}$
0	OFF	27.3	26.3	25.8	25.8	−1.0
10	ON	27.3	26.2	31.0	30.0	+3.8
20	ON	29.4	27.0	33.7	34.1	+5.7
30	ON	29.7	28.7	38.2	41.5	+10.7
40	ON	31.2	31.6	42.6	44.8	+12.3
50	ON	33.1	34.1	45.7	44.1	+11.3
60	ON	37.1	37.0	48.8	46.7	+10.7

4 Photographic Documentation (5 Collages, 19 Frames)

Collage C1 — BASELINE + SENSOR SETUP (4 frames). Video: TikTok link above. **[F1, t=00:01]:** Medical ambient thermometer: 26.0 °C. System at thermal equilibrium. Tramontina triple-bottom pot with 1 L pure water on gas stove, flame OFF. Two probe thermometers inserted vertically, tips touching pot bottom. **[F2, t=00:09]:** IR1 (yellow handheld) aimed at water surface: 25.8 °C. Second IR (black handheld) visible. Probes: t1 = 27.3 °C (fast), t2 = 26.3 °C (standard). Four independent readings at equilibrium. **[F3, t=00:12]:** IR2 confirms 25.8 °C. Cross-validated: IR1 = IR2 = 25.8 °C. Bottom slightly warmer than surface ($\Delta \approx +1$ °C) — classical expectation at equilibrium. **[F4, t=00:25]:** Gas flame ignited. Blue flame visible under pot. All four sensors operational. Experiment begins. **BASELINE FUNCTION:** Establishes that the "normal" pre-flame gradient has bottom *warmer* than surface. Every subsequent frame documents the *inversion* of this gradient.

Collage C2 — FIRST 40 SECONDS: GRADIENT INVERSION ONSET (4 frames). [F1, t=10 s]: t1 = 27.3 (UNCHANGED), t2 = 26.2 (DECREASED −0.1 °C), IR1 = 31.0, IR2 = 30.0. **CRITICAL:** 10 s of max flame, bottom has NOT heated. t2 has *cooled*. Surface jumped +4.7 °C. Gradient inverted: $\overline{\Delta} = +3.8$ °C. **[F2, t=20 s]:** t1 = 29.4, t2 = 27.0, IR1 = 33.7, IR2 = 34.1. Bottom finally rising. Surface leads by +5.7 °C. **[F3, t=30 s]:** t1 = 29.7, t2 = 28.7, IR1 = 38.2, IR2 = 41.5. Gap widening. $\overline{\Delta} = +10.7$ °C. **[F4, t=40 s]:** t1 = 31.2, t2 = 31.6, IR1 = 42.6, IR2 = 44.8. **PEAK INVERSION: $\overline{\Delta} = +12.3$ °C.** Surface twelve degrees hotter than bottom, with heat applied at the bottom.

Collage C3 — t = 50–80 s: SUSTAINED INVERSION (4 frames). [F1, t=50 s]: t1 = 33.1, t2 = 34.1, IR1 = 45.7, IR2 = 44.1. $\overline{\Delta} = +11.3$ °C. **[F2, t=60 s]:** t1 = 37.1, t2 = 37.0, IR1 = 48.8, IR2 = 46.7. $\overline{\Delta} = +10.7$ °C. **[F3, t=70 s]:** t1 = 40.5, t2 = 40.4, IR1 = 51.3, IR2 = 48.5. $\overline{\Delta} = +9.5$ °C. **[F4, t=80 s]:** t1 = 43.6, t2 = 42.6, IR1 = 53.8, IR2 = 51.0. $\overline{\Delta} = +9.3$ °C. Gradient narrowing from +12.3 to +9.3 °C but still inverted after 80 s.

Collage C4 — t = 90–120 s: CONVERGENCE BEGINS (4 frames). [F1, t=90 s]: t1 = 45.0, t2 = 45.7, IR1 = 55.5, IR2 = 52.6. $\overline{\Delta} = +8.7$ °C. **[F2, t=100 s]:** t1 = 48.2, t2 = 48.5, IR1 = 58.1, IR2 = 56.3. $\overline{\Delta} = +8.9$ °C. **[F3, t=110 s]:** t1 = 51.9, t2 = 51.0, IR1 = 59.7, IR2 = 57.9. $\overline{\Delta} = +7.4$ °C. **[F4, t=120 s]:** t1 = 52.9, t2 = 53.7, IR1 = 62.0, IR2 = 58.9. $\overline{\Delta} = +7.2$ °C. Two full minutes of heating: bottom still 7+ °C colder than surface.

Collage C5 — t = 130–150 s: FINAL STATE (3 frames). [F1, t=130 s]: t1 = 56.8, t2 = 56.5, IR1 = 63.6, IR2 = 59.7. $\overline{\Delta} = +5.0$ °C. **[F2, t=140 s]:** t1 = 58.2, t2 = 58.8, IR1 = 64.7, IR2 = 65.8. $\overline{\Delta} = +6.8$ °C. **[F3, t=150 s]:** t1 = 62.1, t2 = 63.8, IR1 = 67.2, IR2 = 67.2. $\overline{\Delta} = +4.3$ °C. **FINAL STATE:** After 150 s of maximum flame, surface STILL +4.3 °C hotter than bottom. Classical prediction (bottom hottest) not achieved at any point during observation.

5 Anomaly Analysis

Anomaly W16-1: Bottom does not heat in first 10 s. t1 unchanged (27.3 °C), t2 *decreased* (26.3 → 26.2 °C). Max flame, direct contact via SS triple-bottom. Reproduces Exp. 5 pattern in pure water. Composition eliminated.

Anomaly W16-2: Surface > bottom for 150 s continuous. Peak $\overline{\Delta} = +12.3$ °C at $t = 40$ s. Never reverses. Classical prediction: bottom always hottest. Observation: surface always hottest.

Anomaly W16-3: Identical to Exp. 5 without organic matter. The objection "beans/lentils cause anomalous convection" is falsified. Pure water, same pot type, same flame, same instrumentation — same inverted gradient.

6 Falsification Table

Classical Prediction	Observation	Mechanism	Status
Bottom is hottest point	Surface +3.8 to +12.3 °C hotter	4-sensor, 150 s	FALSIFIED
T rises monotonically at bottom	t2 decreases 0.1 °C in 10 s	Reproduced from Exp. 5	FALSIFIED
Inverted gradient = composition artifact	Pure water, identical pattern	Control experiment	ELIMINATED
$\vec{F} = -k_T m \nabla T$	Cold attracted to bottom, hot ejected to surface	All data consistent	CONSISTENT

7 Conclusion

Experiment 16: 4 sensors, pure water, 150 s, max flame. Surface hotter than bottom from $t = 10$ s (+3.8 °C) to $t = 150$ s (+4.3 °C), peak +12.3 °C at $t = 40$ s. Bottom stagnates/decreases in first 10 s. Reproduces Exp. 5 anomalies without organic matter. Three classical predictions falsified. Consistent with thermal force law.
